5.14 Transmission Line Safety and Nuisance

This section discusses safety and nuisance issues associated with the transmission line that will interconnect the PHPP with the regional grid. The section discusses general aspects of the Project transmission system and also addresses electric and magnetic fields for the various transmission line segments.

5.14.1 LORS Compliance

This section provides a list of applicable laws, ordinances, regulations, and standards (LORS) that apply to the proposed transmission line, substations and engineering. The Project will comply with the applicable LORS during construction and operation.

5.14.1.1 Design and Construction

Table 5.14-1 lists the applicable LORS for the design and construction of the proposed transmission line.
Electrical Clearances

Typical high-voltage overhead transmission lines are composed of bare conductors connected to supporting structures by means of porcelain, glass, or composite insulators. The air surrounding the energized conductor acts as the insulating medium. Maintaining sufficient clearances, or air space, around the conductors to protect the public and utility workers is paramount to the safe operation of the line. The safety clearance required around the conductors is determined by normal operating voltages, conductor temperatures, short-term abnormal voltages, windblown swinging conductors, contamination of the insulators, clearances for workers, and clearances for public safety. Minimum clearances are specified in the California Public Utility Commission (CPUC) General Order 95 (GO-95). Electric utilities, State regulators, and local ordinances may specify additional (more restrictive) clearances. Typically, clearances are specified for the following:

- Distance between the energized conductors themselves,
- Distance between the energized conductors and the supporting structure,
- Distance between the energized conductors and other power or communication wires on the same supporting structure, or between other power or communication wires above or below the conductors,
- Distance from the energized conductors to the ground and features such as roadways, railroads, driveways, parking lots, navigable waterways, airports, etc.,
- Distance from the energized conductors to buildings and signs, and
- Distance from the energized conductors to other parallel power lines.

Substation Design

One new substation will be constructed at the PHPP plant site. In addition, there will be a bay addition to the existing SCE Vincent Substation to accommodate the new line from the PHPP. These upgrades will be designed to comply with the applicable standards.

5.14.1.2 Electric and Magnetic Fields (EMF)

5.14.1.6 Involved Agencies and Required Permits

Table 5.14-6 identifies Federal, State, and local agencies with jurisdiction to issue permits or approvals, conduct inspections, and/or enforce the above-referenced LORS. Table 5.14-6 also identifies the responsibilities of these agencies as they relate to Project construction, operation, and maintenance. No specific permits are required that relate specifically to transmission line safety and nuisance issues that are not discussed in other sections of the AFC.

5.14.2 Affected Environment

Section 2.5 of the Project Description provides a description of the two transmission line segments planned for the PHPP. Diagrams are provided in Section 2.5 that show Segment 1 will cross an area where no other transmission lines currently exist. Segment 2 will provide a consolidation of the existing SCE Vincent-Pearblossom 230-kV line with the new Project line to the Vincent Substation. Segment 1 will require a new right-of-way (ROW) and Segment 2 will involve upgrades to an existing transmission line that already is present in an existing SCE transmission corridor that already contains multiple transmission lines.
5.14 Transmission Line Safety and Nuisance

5.14.3 Impact Analyses

5.14.3.1 Electrical Effects

The electrical effects of high-voltage transmission lines fall into two broad categories: corona effects and field effects. Corona is the ionization of the air that occurs at the surface of the energized conductor and the attachment hardware due to very high electric field strength at the surface of the metal during certain conditions. Corona may result in radio and television reception interference, audible noise, light, and production of ozone. Field effects are the voltages and currents that may be induced in nearby conducting objects. A transmission line's inherent electric and magnetic fields cause these effects.

5.14.3.2 Electric and Magnetic Fields

Operating power lines, such as the energized components of electrical motors, home wiring, lighting, and all other electrical appliances, produce electric and magnetic fields, commonly referred to as electromagnetic field (EMF). The EMF produced by the alternating current electrical power system in the United States has a frequency of 60 hertz (Hz), meaning that the intensity and orientation of the field changes 60 times per second.

Electric fields around transmission lines are produced by electrical charges on the energized conductor. Electric field strength is directly proportional to the line's voltage; that is, increased voltage produces a stronger electric field. At a given distance from the transmission line conductor, the electric field is inversely proportional to the distance from the conductors, so that the electric field strength declines as the distance from the conductor increases. The strength of the electric field is measured in units of kilovolts per meter (kV/m). The electric field around a transmission line remains steady and is not affected by the common daily and seasonal fluctuations in usage of electricity by customers.

Magnetic fields around transmission lines are produced by the level of current flow through the conductors, measured in terms of amperes. The magnetic field strength is also directly proportional to the current; that is, increased amperes produce a stronger magnetic field. The magnetic field is inversely proportional to the distance from the conductors, and thus, like the electric field, the magnetic field strength declines as the distance from the conductor increases. Magnetic fields are expressed in units of milligauss (mG). The amperes and, therefore the magnetic field around a transmission line, fluctuate daily and seasonally as the usage of electricity varies.

Considerable research has been conducted over the last 30 years on the possible biological effects and human health effects from EMF. This research has produced many studies that offer no uniform conclusions about whether long-term exposure to EMF is harmful or not. In the absence of conclusive evidence, some states, California in particular, have chosen not to specify maximum acceptable levels of EMF. Instead, California mandates a program of prudent avoidance whereby EMF exposure to the public would be minimized by encouraging electric utilities to use low-cost techniques to reduce the levels of EMF.

**EMF Assumptions**

It is important that any discussion of EMF include the assumptions used to calculate the values and to remember that EMF in the vicinity of power lines varies based on a variety of factors including, line design, the presence of other lines in the ROW, line loading, and distance from the line. The electric field depends upon the line voltage. An actual voltage of 220-KV is used in the calculations for this EMF study while 230 kV has been used nominally throughout this AFC. The Los Angeles Department of Water and Power utilizes the nominal voltage of 220-kV, while SCE uses 230-kV. The use of either voltage in this
document is consistent with the industry use of the 230-kV term to describe the nominal voltage for this class of system.

The magnetic field is proportional to the line loading (amperes), which varies based on the interconnected power system loading, and the power output of the generating facility as output changes to meet increases or decreases in demand for electric power. The line loading values were based on the maximum load carrying capability of each line section, which will produce a worst case value for the magnetic field.

The arrangement of the transmission lines in the ROW is another important consideration for the field calculation. The assumed phase arrangement of each line has been entered into the model used for the field calculation. As such, there will be some field calculation where adjacent lines on double-circuit towers are configured with phases A, B, and C arranged horizontally or from top to bottom, while the other circuit is configured with phases C, A, and B from top to bottom.

**EMF Calculations**

EMF values were calculated at three feet above the flat terrain using the “Fields” program developed by SCE. Measurements for electric and magnetic fields at three feet above the ground are in accordance with the Institute of Electrical Engineers (IEEE) standards, and the SCE program also was developed in accordance with the IEEE standards. The program calculates the electric fields expressed in volts or kilovolts per meter (kV/M) and the magnetic fields expressed in milli-Gauss (mG). The various inputs for the calculations include voltage, maximum load in amperes, current angle (phasing), conductor diameter and spacing, number of sub-conductors for bundled lines, along with relative location of conductors and shield wires. The elevation used for the conductors is the attachment height at the structure. Table 5.14-7 shows the input values for modeling.

### 5.14.3.3 Audible Noise

Corona may result in the production of audible noise from a transmission line. Corona is a function of the voltage of the line, the diameter of the conductor, and the condition of the conductor and suspension hardware. The electric field gradient is the rate at which the electric field changes and is directly related to the line voltage.

The electric field gradient is greatest at the surface of the conductor. Large-diameter conductors have lower electric field gradients at the conductor surface and, hence, lower corona than smaller conductors, everything else being equal. Also, irregularities (such as nicks and scrapes on the conductor surface) or sharp edges on suspension hardware concentrate the electric field at these locations and, thus, increase corona at these spots. Similarly, contamination on the conductor surface, such as dust or insects, can cause irregularities that are a source for corona. Raindrops, snow, fog, and condensation are also sources of irregularities. Corona typically becomes a design concern for transmission lines having voltages of 345-kV and above. Since the Project will be connected at 230-kV, it is expected that no corona-related design issues will be encountered.

The construction and operation of the PHPP, including its interconnection with SCE’s transmission system, is not expected to result in significant increases in EMF levels or audible noise.

### 5.14.3.4 Induced Current and Voltages

A conducting object, such as a vehicle or person in an electric field, will experience induced voltages and currents. The strength of the induced current will depend on the electric field strength, the size and shape of the conducting object, and the object-to-ground resistance. When a conducting object is isolated from the ground and a grounded person touches the object, a perceptible current or shock may occur as the current flows to ground. Proper design standards will be implemented to prevent hazardous and nuisance shocks by ensuring that metallic objects on or near the right-of-way are grounded and that sufficient clearances are provided at roadways and parking lots to keep electric fields at these locations low enough to prevent vehicle short-circuit currents from exceeding 5 milliamperes (mA).

Magnetic fields can also induce voltages and currents in conducting objects. Typically, this requires a long metallic object, such as a wire fence or above-ground pipeline that is grounded at only one location. A person who closes an electrical loop by grounding the object at a different location will experience a shock similar to that described above for an ungrounded object. Design standards for managing this issue dictate multiple grounds on fences or pipelines, especially those that are oriented parallel to the transmission line.

The PHPP 230-kV transmission interconnection will be constructed in conformance with CPUC GO-95 and Title 8 CCR 2700 requirements. These regulations require sufficient grounding to ensure that hazardous shocks do not occur. Therefore, hazardous shocks are unlikely as a result of Project construction, operation, or maintenance. A shield wire will be installed as a feature of the PHPP.
5.14 Transmission Line Safety and Nuisance

5.14.3.5 Communications Interference
Corona caused by the power line can cause interference with radio and television reception. The line will be designed to minimize corona noise by proper selection of the conductor and associated hardware. Pre-construction surveys of ambient noise levels will be performed, and then compared to the noise levels after construction. Interference complaints from the public will be investigated, and repairs made as needed to resolve the interference complaint.

5.14.3.6 Aviation Safety
The PHPP is located immediately adjacent to Air Force Plant 42. The Project contacted the Southern California Logistics Airport (SCLA), located in nearby Victorville, CA, because the High Desert Power Project is located immediately adjacent to SCLA. Appendix E contains a letter from SCLA’s Airport Operations Supervisor stating that the HDPP has not posed “any hazard to aircraft operations” (Heldreth, 2005). As EMF issues that affected aircraft communications or avionics likely would be considered a hazard to aircraft operations, it is reasonable to assume that such issues have not arisen for HDPP. As EMF issues for the PHPP would be similar to those associated with HDPP because of the similarities between the two projects, it is expected that Project transmission line impacts on aviation safety would be less than significant. The design of the PHPP transmission system will incorporate the needed measures to ensure aviation safety.

5.14.3.7 Fire Hazards
The proposed 230-kV transmission interconnection lines will be designed, constructed, and maintained in accordance with the CPUC’s GO-95, which establishes clearances from other man-made and natural structures as well as tree-trimming requirements to reduce/avoid fire hazards. SCE will maintain the transmission line corridor and immediate area in accordance with existing regulations and accepted industry practices that will include identification and abatement of any fire hazards.

5.14.4 Mitigation Measures
No significant transmission line-related safety or nuisance impacts were identified as a result of the Project studies.

The PHPP will be designed, constructed, operated, and maintained in accordance with the applicable LORS and to minimize EMF at the edges of the right-of-way. Impacts will be less than significant with Project implementation as described in this section (e.g., insulators and hardware selected to minimize corona noise; pre- and post-Project noise surveys performed to document ambient condition change caused by the line, and procedures to investigate and resolve interference complaints). No additional mitigation is required. However, should additional currently unforeseen issues arise, they will be addressed to ensure that impacts remain less than significant.
